Abstract - Recently, the rapid development of transform-based coding has improved the performance of hyperspectral image sensors. Each hyperspectral image has a size of more than a hundred MB, which needs to be compressed before the transmission to save the data transmission bandwidth, reduce the sensor complexity, increase the sensor performance, and lower the energy consumption. This work proposed a novel lossy hyperspectral image compression algorithm, which has high coding efficiency, decreases coding complexity and reduces overall memory (coding and transform) demand. The Segmented Fractional Wavelet Filter (SFrWF) is a low-memory mathematical transform approach to compute the transform coefficient of the hyperspectral image. The Low Complexity Zero Memory Set Partitioned Embedded bloCK (LC-ZM-SPECK) is employed to code coefficients of the transform hyperspectral image, which is applied on a frame-by-frame basis. The simulation result shows that the proposed compression algorithm is faster than other state-of-the-art compression algorithms, making it an appropriate choice for low hardware resource hyperspectral image sensors.

Keywords - Sensor performance, Transform memory, Transform coding, Hyperspectral image compression, Set partitioned algorithm.

1. Introduction

A HyperSpectral (HS) image includes a hundred to thousands of frequency frames with rich spectral and spatial information for a single scene [1-2]. Because the HS image contains hundreds of pieces of reflection information at various frequencies for each pixel [3], it is well suited for a wide variety of practical applications such as agriculture production (crops variability) [4], archaeological analyses [5], biomedicine [6], cultural heritage [7], disaster prediction & assessment [8], food quality assessment [9], forestry (vegetation coverage) [10], forensic research [11], map revision (land mapping) [12], maritime resources management [13], medical diagnosis [14], meteorological forecasting [15], military target detection [16], mining (identification of minerals) [17], oil & gas exploration [18], pharmaceuticals [19], urban planning [20], verification of documents [21], water quality analysis [22] etc. Besides the mentioned applications, remote sensing (earth observation) is one of the growing applications of HS images where the researchers develop the computer-based algorithm associated with the HS image classification [23], HS image compression [24], HS image change detection [25], HS image feature extraction [26], HS image object detection

[27], HS image segmentation [28], target identification [29], denoising [30] etc.

Unlike color images that record R, G and B channels per pixel, hyperspectral images record hundreds of channels per pixel, representing pixel's spectra [31]. This would imply that HS images demand storage space that is two orders of magnitude greater than required to store colour or multispectral images of a comparable size [32]. Thus, an efficient algorithm for capturing, storing, transmitting, and analyzing HS images is required [33].

The large redundant information in HS image data must be removed to achieve a satisfactory HS image compression performance. A very high spectral correlation exists between the nearby (adjacent) frequency frames, while the spatial correlation presents between the neighbourhood pixels in the same frequency frame [34, 35]. These correlations are exploited by the HyperSpectral Image Compression Algorithm (HSICA) to reduce the redundancy in HS images [36]. The main objective of any compression algorithm is to reduce the image data for the reconstruction of the HS image after the compression process and improve

the image sensor's performance by reducing the processing time and power computation [37, 38]. The low complexity of the compression algorithm requires minimum data processing time and power computation [39].

In the subsequent sections, Section 2 presents a literature review by other researchers on the different compression algorithms for HS images. At the same time, related work is covered in the next section of the manuscript. The proposed HSICA is covered in detail with the associated pseudocode and flow figure (section 4). The experimental result and comparative study with state of art HSICA are covered in Section 5. Finally, Section 6 entails the concluding remarks of this work.

2. Literature Review

In the past two decades, many Hyperspectral Image Compression Algorithm (HSICA) have been proposed. They are broadly classified by the way the compression algorithm operates (predictive coding, vector quantization-based coding, transform coding, compressive sensing, tensor decomposition, leaning-based coding or hybrid coding algorithms) or based on data loss (lossless, lossy and near-lossless) [36].

The lossy, lossless or near-lossless compression algorithm is split based on the compression ratio or by the loss of the data [40]. The Compression Ratio (CR) is the original HS image's size compared to the reconstructed HS image [41]. In the lossless HS image compression, there is no image data loss, and the reconstructed HS image is similar to the original HS image. The value of CR is very low and almost near one to three [42]. The near-lossless HS image compression has caused the loss of some HS image data, but the reconstruction of the HS image is almost similar to the original HS image. Such HS image degradations are nearly invisible to human observers. These compression algorithms have a slightly higher CR than lossless HS image compression algorithms [43]. Lossy HS image compression algorithms have a loss of significant HS image data, but it has high CR [44]. The CR of these compression algorithms is related to the bit rates [45].

The Predictive Coding (PC) [49], Vector Quantization (VQ) based coding [47], Transform Coding (TC) [48], Compressive Sensing (CS) based coding [49], Tensor Decomposition (TD) based coding [50], Leaning based Coding (LC) [51] or Hybrid Coding (HC) algorithms [52] are classified based on the coding process of the compression [53].

In predictive coding, HSICA calculates the prediction error through the predictor. This predictor exploits the spectral correlation between the continuous frequency frames [57]. These HSICAs are data-dependable and

perform only lossless HS image compression. Variable Length Coding (VLC) and Lookup Tables (LUT) are the major predictive coding-based HSICAs [46].

The VQ-based HSICA uses a coding book to achieve compression of the HS image. This codebook is present at the decoder and encoder end. The codebook differs in the compression of every HS image. HS image is partitioned into small blocks, and a specific code or symbol is given to the block throughout the training process. The HS image is reconstructed with the help of the codebook [47].

Compression of HS image through the CS-based coding algorithm is achieved in the three steps. The encoder of HSICA sensed the HS image and changed the 3D HS image into a small 2D data matrix. Again, the 2D data matrix is covered in a small data matrix. This small data matrix is transmitted to the communication channel. This process is repeated till the entire HS image gets transmitted. The decoder reconstructs the HS image when all the HS image data is received from the encoder end [49].

The TD-based HSICA uses a tensor (3D matrix) to decompose the HS image into small dimensions. These tensors of smaller dimensions are encoded, and their transmission is carried out through the channel [50].

The deep learning and machine learning methods are used in the LC-based HSICA. These compression algorithms also use the neural network (convolutional, recurrent, autoencoder, feedforward, multilayer perceptron) [54]. It has high coding efficiency with moderate CR. These HSICA have very high coding complexity and coding memory requirements. It also requires the other hardware resources [51].

The hybrid coding compression algorithms combine two or three techniques to achieve compression. Neural networks with predictive coding and neural networks with transform coding are the major combinations frequently used to design the HSICA [52].

The Transform Coding (TC) based HSICA uses mathematical transform (Wavelet, Curvelet, Fourier, Cosine, Shearlet) to convert the HS image to the frequency domain [55-59]. The energy is packed into a few coefficients through this transforming process (works as a decorrelator). These compression algorithms can work for lossless and lossy compression and have high CR [39]. The mathematical transform converts the correlation frequency frames into the energy-concentrated uncorrelated transform coefficients. Although high computed transform is complex, the associated coding algorithm is highly efficient and low complex. For the compression of HS images, many types of mathematical transform are used in a different working fashion, which depends upon the requirement of the

application [40]. The 3D dyadic wavelet transform has good energy clustering in the space and time domain [60, 61]. Many other derived mathematical transforms, such as the lapped transform [62], are also used to achieve the compression of HS images. 3D-Set Partitioning Embedded Block (3D-SPECK) [63], 3D-Listless SPECK (3D-LSK) [64], 3D-Set Partitioning In Hierarchical Trees (3D-SPIHT) [65], 3D-No List SPIHT (3D-NLS) [66], 3D-Wavelet Based Tree Coding (3D-WBTC) [67], 3D-Low Memory Block Tree Coding Algorithm (3D-LMBTC) [68], 3D-Zero Memory Set Partitioning Embedded Block (3D-ZM-SPECK) [69], Fractional Wavelet Filter based Zero Memory Set Partitioning Embedded Block [70], 3D-Listless Embedded Zerotree Set Partitioning Coding (3D-LEZSPC) [56], 3D-Block Partitioning Embedded Coding (3D-BPEC) [40] are the famous transform based HSICAs.

Recently, a fractional wavelet filter was used to exploit the spatial decorrelation of HS images, while spectral decorrelation was removed by the prediction methodology [70-72]. It has been observed that with the use of a 2D fractional wavelet filter with 2D (2D-ZM-SPECK) [45], the coding efficiency of the compression algorithm increases with low coding memory and coding complexity. However, this compression algorithm has moderate transform memory, which is reduced by the use of SFrWF, and the complexity of the compression algorithm is reduced by storing the most significant coefficient of each subband for every frequency frame in the buffer memory [73, 74]. Through this buffer memory, the complexity of the proposed HSICA is reduced significantly compared to that of FrWF-based HSICA [75].

3. Related Work

The associated wavelet filter is covered in the first phase of this section, followed by linear indexing and the last in-depth description of the 2D-LC-ZM-SPECK [76].

3.1. Segmented Fractional Wavelet Filter (SFrWF)

The transformation of 3D images (hyperspectral image, magnetic resonance imaging, etc.) is a complex process that generates many terraform image data. It also has high complexity, depending on the image data [39, 76]. Because the 3D-DWT is applied directly to the complete HS image, the traditional technique of calculating the wavelet coefficients of HS images requires a massive memory [77]. The requirement of memory escalates rapidly with the high dimension HS image or level of wavelet transform. [67]. However, onboard HS image sensors suffer from low hardware resources [56]. Many other ways of wavelet transformation have been proposed to lower the coding complexity. The lifting approach to calculating the wavelet transform has been proposed, which is less complex and generates almost the same type of transform coefficients. Dyadic wavelet transform and integral wavelet transform

had slightly higher complexity, but they had better energy compaction of the transform coefficients [68]. It has been known that an HS image is a combination of 2D frequency frames that are taken for a single scene [78]. Thus, they have a very high spectral correlation. 2D discrete wavelet transform (2D-DWT) has lower transform memory requirement and complexity, but they fail to remove the spectral correlation, reducing the coding efficiency [70, 79]. The same strategy has also been implemented for medical images [80]. However, using a predictor with 2D-DWT, the compression algorithm has a higher coding efficiency.

Still, 2D-DWT has a high transform memory demand, making it an unsuitable candidate for onboard sensors [70]. To solve the above-mentioned issues, three different approaches have been made: the line-based approach [81], the block-based approach [82], and the stripe-based approach [83]. In order to reduce the demand for memory for the computation of wavelet coefficients, the line-based DWT implements the lifting algorithm [82]. Applying the DWT to individual blocks, as opposed to the complete image, is yet another method for decreasing the required memory [82]. The line-based wavelet transform coefficients are saved in strip buffers in the modified version of the line-based discrete wavelet transform known as the strip-based discrete wavelet transform. This helps save memory [83]. The first two approaches have the exact transform memory requirement, but the last approach compresses high-resolution images and videos [81-84]. Recently, the DWT has been computed using the Fractional Wavelet Filter (FrWF), which is implementable on low-cost sensor nodes and requires far less memory than the approaches before it [71]. Even though the FrWF alleviates the memory constraints of low-cost portable devices and sensor nodes for HS images, the memory needs of the FrWF are significantly higher than the amount of memory often accessible on sensor nodes [85].

The SFrWF is an advanced method to transform the pixels of an HS image with a low transform memory requirement. It computes the wavelet coefficients differently [75]. Instead of taking frequency frames of the HS image into the buffer memory line by line, the image lines are partitioned into small multiple segments, and these segments will go one by one in the buffer for the calculation of wavelet transform [73]. The overlap-add method is used to combine the individual segments into one. There are nine different buffers (one input buffer, four buffers for filter coefficients, and four immediate buffers) used to calculate the wavelet coefficients in the SFrWF. Apart from these buffers, one more buffer is required to hold the convolution result [75]. The amount of memory that the SFrWF needs to operate is determined by the number of elements saved in the nine buffers and the size of each element [73]. Table 1 covers the transform memory requirement by the different transform with the coding memory of associated HSICA.

Table 1. Requirement of the memory required by the HS image coder when different types of wavelet transform and HSICAs are combined for encoding and decoding process

HS Image Coder			
Transform Stage	Coding Stage	HS Image Resolution	Required Memory
Conventional 3D Wavelet Transform	Any HSICA	Any Resolution	Conventional 3D Wavelet Transform
Conventional 2D Wavelet Transform	List Based HSICA	Low Resolution	Conventional 2D Wavelet Transform
		High Resolution	List Based HSICA
	3D-LSK	Any Resolution	According to the compression algorithm
	2D-ZM-SPECK	Any Resolution	Conventional 2D Wavelet Transform

3.2. Mathematical Transform Based Set Partition Hyperspectral Image Compression Algorithms (MT-SP-HSICA)

The MT-SP-HSICAs are a special compression algorithm that uses the set structure of transform HS image to achieve the compression. The mathematical transform exploits the correlation of the HS image and transforms the HS image into a few high-energy coefficients [36].

The MT-SP-HSICAs have multiple noticeable advantages over the other HSICAs, which are as follows.

- The MT-SP-HSICA starts from the most significant bit plane. Execution continues until the last bit plane is finished or the bit budget is fully consumed [34].
- The MT-SP-HSICA works at any bit rate. The reconstruction process generates the HS image at a lower bit rate post-compression. [56].
- The MT-SP-HSICA uses the set structure and partitions the transformed HS image into the partition rule (zeroblock cube, zero trees or zeroblock cube tree). With this, a single bit represents many insignificant coefficients [36].
- Since a single bit represents countless minor/inconsequential coefficients at low bit rates, these algorithms maintain strong compression performance [39].
- The MT-SP-HSICA has a lower coding complexity than other types of HSICA [40].

According to the set partition rule, the MT-SP-HSICA can be classified into three subcategories: zeroblock cube, zero trees and zeroblock cube tree [34]. The zeroblock cube method partitioned the transformed HS image into connecting block cubes. In contrast, the zero tree method groups transform coefficients corresponding to the analogous location and form the Spatial Orientation Tree (SOT) [68]. The zeroblock cube tree method uses the best features of the zeroblock cube and zero trees. It then divided the HS image into connecting block cubes, and after that, it created block cube trees in a zero tree pattern with the roots in the uppermost sub-band [34]. 3D-SPECK [63], 3D-LSK [64] and 3D-ZM-SPECK [73] belong to the zeroblock coding, while 3D-SPIHT [65] and 3D-NLS [66] belong to

the zero tree coding. 3D-WBTC [67], 3D-LMBTC [68], and 3D-LCBTC [34] belong to the zeroblock cube tree coding.

3.3. Linear Indexing

Linear indexing (Morton mapping or Z scan) converts a dimension transform matrix or three-dimensional transform matrix into a single-dimension array [70]. The HS image is converted into a 3D transform matrix using the wavelet transform, in which the sub-bands are grouped in a pyramidal shape. The sub-bands with a lower resolution can be found at the very top of the pyramid, while sub-bands with a higher resolution can be found closer to the base of the pyramid structure [39]. LLL sub-band is placed at the start of the 1D array [34].

3.4. 2D-Low Complexity Zero Memory Set Partitioned Embedded block (2D-LC-ZM-SPECK)

The 2D-LC-ZM-SPECK is a low complexity version of the 2D-ZM-SPECK. It follows the same partition rule as 2D-SPECK [86] and 2D-LSK [87] and utilises the good features of linear coindexing of the transform coefficients. Through this, the proposed HSICA does not require lists, state tables, or markers to track the sets or coefficients. It has been noted that 2D-ZM-SPECK checks the significance of sets or coefficients for each bit plane. This increases the complexity of the compression algorithm. To reduce complexity, a maximum magnitude of each sub-band is saved in a buffer memory, which is used to test the significance of the sub-band.

Let us assume the HS image is transformed frame by frame through the 'L' level segmented fractional wavelet filter. An additional buffer memory is named M_{mem} of $[(3L+1) \times \gamma]$ elements, each having eight bytes to store the highest value of the sub-band. The first transform level generates four sub-bands, one LL sub-band (approximation subband), while the other three sub-bands are considered detail sub-bands. For the next transform level, the LL sub-band of the frequency frame is partitioned into four new sub-bands, and a new approximation sub-band is created. The detail sub-bands of the transform coefficients are grouped hierarchically in three different orientations, which are represented as LH_{ω} , HL_{ω} and HH_{ω} ; $\omega = 1, 2, 3, \dots, L$.

The initial sub-bands are arranged in the form of S_ϕ^ω & I^ω . The i^{th} element of the γ^{th} frequency band is denoted as $M_{\text{mem}}(i, \gamma)$ where $M_{\text{mem}}(0, 0)$ represents the LL sub-band of the first frequency frame while other sub-bands of the frequency frames are calculated as ' $i = [3(L - \omega) + \phi]$ '. It depends on the pyramidal position and orientation of sub-bands. Through the use of buffer memory, the computational complexity of the proposed HSICA is reduced significantly, reducing the sensor power consumption and requirement of the hardware resources. The encoding process of HSICA starts from the comparing values of first frequency frames of initial $M_{\text{mem}}(0, 0)$ and $\max[M_{\text{mem}}(i, 0); i = 0, 1, 2, 3, \dots, 3L+1]$ against the top bit plane. The first 'S' and 'I' set is defined as S_0^L & I^L . If

the 'S' set is significant to the ongoing threshold, it is quad-partitioned into four new 'S' sets. If the 'I' set is significant against the current threshold, then it will be partitioned into three new 'S' sets and a new 'I' set as $S_1^{L-1}, S_2^{L-1}, S_3^{L-1}$ & I^{L-1} . The buffer memory is now used to calculate the significance of the newly formed 'S' and 'I' sets. This process is repeated for the other transform HS image frequency frames and will continue when the last bit plane encoded or bit budget is available. The significance of 'S' $\{S_\phi^\omega\}$ set and I $\{I^\omega\}$ set is measured against the ongoing threshold is calculated with the Eq 1 & Eq 2. While the set produced by the significant 'S' set partitioning is calculated as in Eq 3.

$$\Lambda_n(S_\phi^\omega) = \begin{cases} 0 & \text{if } M(i) < \eta \\ 1 & \text{if } \eta < M(i) < 2\eta \\ \text{NULL} & \text{if } M(i) < 2\eta \end{cases} \quad \begin{matrix} i=3(L-\omega)+\phi \\ i=3(L-\omega)+\phi \\ i=3(L-\omega)+\phi \end{matrix} \quad (1)$$

$$\Lambda_n(I^\omega) = \begin{cases} 0 & \text{if } M(i) < \eta \\ 1 & \text{if } \eta < M(i) < 2\eta \\ \text{NULL} & \text{if } M(i) < 2\eta \end{cases} \quad \begin{matrix} i=3(L-\omega)+\phi:3L \\ i=3(L-\alpha)+\phi:3L \\ i=3(L-\alpha)+\phi:3L \end{matrix} \quad (2)$$

$$\Lambda_n(S) = \begin{cases} 1 & \text{if } \eta \leq \max_{i \in S}(|S(i)|) < 2\eta \\ 0 & \text{if } \max_{i \in S}(|S(i)|) < \eta \\ \text{NULL} & \text{if } \max_{i \in S}(|S(i)|) > 2\eta \end{cases} \quad (3)$$

This same process is followed by the other frequency frames before the compression algorithms' encoding starts. By combining the sorting pass with the refinement pass, 2D-LC-ZM-SPECK does not employ the LSP.

A brief description of the different state-of-the-art MT-SP-HSICA for the compression of HS images is presented in Table 2.

4. Encoding Process of Proposed Algorithm

An unprocessed HS image (captured at the onboard sensor) is transferred to the frequency domain through a 2D SFrWF frame (L level) by frame. Through this process, the requirement of the transformed memory is reduced. A new Modified HS (MHS) image cube (the same size as the

original HS image) is generated by gathering eight continuous frames. The first frequency frame is taken as it is, but the rest are taken differently. From the second frame the second frame of MHS differs between the second and first frames. This procedure is repeated for the remaining six frames of the slice of eight frames. For the generation, the rest of the frames in MHS are taken as a slice of eight continuous HS image frames and repeated until the last frame. The linear indexing scheme changes the MHS to the single-dimension array. Each frame of the MHS is encoded with the 2D-LC-ZM-SPECK. This process is repeated frame by frame (according to the bit plane) till the bit budget is obtainable. The associated pseudo code of proposed HSICA is covered in Table 3. The encoding procedure of the proposed HSICA is covered in Figure 1.

5. Simulation Result & Analysis

To test the feasibility and validity of this HSICA, extensive experimental HS image data comparison and analysis are presented in this manuscript. Six HS image datasets were chosen for the experiments to compare the proposed HSICA with eight HSICAs and analyse associated impacts on coding efficiency, memory, and complexity.

5.1. Dataset

Six HS images are taken for the simulation test, of which four HS images belong to the Yellowstone dataset. The other two HS images are named Washington DC Mall and Urban. The characteristics of the HS images are summarized in Table 4.

5.2 Performance Evaluation Metrics

The performance of any mathematical transform-based HSICA is measured on the metrics of coding efficiency,

coding memory, transform memory and coding complexity [34]. Image quality assessment metrics, including peak signal-to-noise ratio (PSNR) and structural similarity index measure (SSIM), are used to measure the coding efficiency of hyperspectral image compression algorithms.

The coding complexity of HSICA is defined as the time required for the encoding and decoding the transform coefficients. The coding memory is the requirement of memory by the HSICA to encode/decode the coefficients. It may be a list array or a state table [37].

The original HS image is presented as $X(a,b,c)$ before the HS image compression process. In contrast, after the compression process, the reconstructed HS image is represented as $Y(a,b,c)$.

The Rate-Distortion (RD) performance of any HS image compression algorithm can be evaluated based on the algorithm's coding efficiency. It is calculated as in Eq 4, while the numeric value of the MSE [94, 95] is calculated as in Eq 5.

The symmetrical similarity index, or SSIM, is a metric that compares two HS images (original and reconstructed) to determine how similar they are to one another [96, 97]. Mathematically, it is calculated as in Eq 6.

$$PSNR = 20 \log_{10} \left[\frac{\max\{X(a,b,c)\}}{MSE} \right] \quad (4)$$

$$MSE = \frac{1}{N_{pix}} \sum_{x,y,z} [X(a,b,c) - Y(a,b,c)]^2 \quad (5)$$

$$SSIM(X,Y) = \frac{(2\mu_X\mu_Y + c_1)(2\sigma_{XY} + c_2)}{(\mu_X^2 + \mu_Y^2 + c_1)(\sigma_X^2 + \sigma_Y^2 + c_2)} \quad (6)$$

5.3. Benchmark Hyperspectral Image Compression Algorithms

The proposed HSICA is compared with the state-of-the-art transform-based HSICA 3D-SPECK (CA 1) [63], 3D-SPIHT (CA 2) [65], 3D-WBTC [67] (CA 3), 3D-LSK [64] (CA 4), 3D-NLS [66] (CA 5), 3D-LMBTC [68] (CA 6), 3D-ZM-SPECK [69] (CA 7) and Fraction wavelet filter based ZM-SPECK [70] (CA 8). The simulation result is calculated for different bit rates and presented here on the different performance metrics.

5.4. Implementation Detail

All HSICA are implemented on the computer having the same software and hardware platform. The operating system used for the analysis is Windows 11, which runs on a 20 GB RAM computing device. During the execution, no other simulation was performed to measure the coding complexity. Matlab 2023A is used as a simulation software for the simulation of the HSICAs on the computing device.

Urban	307	307	210	10	HYDICE

5.5. Coding Efficiency

Coding Efficiency is measured using PSNR and SSIM performance metrics. The proposed compression algorithm is zeroblock cube-based MT-SP-HSICA and has the same partition rules as 2D-LSK [87] and 2D-ZM-SPECK. It is clear from Table 5 that the proposed MT-SP-HSICA outperform all state-of-the-art MT-SP-HSICA and is almost the same as the FrWF-based compression algorithm. This is because they generate almost the same encoded coefficients. It has also been noted that the transform coefficient generated by the 2D-DWT, FrWF and SFrWF is similar. Thus, the coding efficiency is the same for the proposed HSICA and FrWF-based HSICA. For other MT-SP-HSICAs, the proposed algorithm outperforms from a range of two dB to three dB at low bit rates, while for high bit rates, coding efficiency differences lie from a range of four dB to five dB. The high coding gain exists because of the non-availability of the highest bit plane in 87.5% of frequency frames due to creating a modified HS image cube. This coding procedure benefit is accomplished by utilising the HS image's inherent spectral redundancy. When the bit budget between the bit planes is exhausted, the suggested compression technique's performance is poor, resulting in a modest drop in the coding gain. The only difference between the proposed HSICA and FrWF-based HSICA is the way of significance testing of the test. Table 6 compares SSIM [96] with the proposed compression algorithm and other MT-SP-HSICA.

5.6. Transform Memory

Transform (wavelet) memory is the memory required by the mathematical transform for calculating (logical, algebraic and arithmetic) the transform coefficients and saving them in the different buffers associated with the mathematical transform. It is clear from Table 6 that the 3D wavelet transform requires much memory, while the calculation of the transform coefficient through the 2D wavelet transform requires less transform memory [98, 99]. It has also been known that 2D wavelet transform works only for the spatial dimension of the HS image and does not remove the associated correlation with the spectral dimension of the HS image [70]. However, the demand for transform memory is still high and needs to be reduced in line with the coding memory. Previously, a fractional wavelet filter was used to calculate the wavelet coefficient in the spatial dimension [70], but it still has high transform memory requirements that must be addressed. The segmented fractional wavelet transform is a special type of fractional wavelet transform that reduces the transform memory requirement. From Table 7, it is clear that SFrWF outperforms other wavelet transform types.

5.7. Coding Memory

HSICA requires memory for the significance / insignificance of the sets or coefficients against the current bit plane level. The MT-ST-HSICAs use either linked lists

[67], state tables [34] or markers [37] for tracking sets or coefficients. 3D-SPECK [63], 3D-SPIHT [65], and 3D-WBTC [67] employ linked lists for tracking of set/coefficients, while 3D-NLS [70], 3D-LSK [64], and 3D-LMBTC [68] use state table and markers for the same task while 3D-ZM-SPECK [69] does not need any markers and linked lists for tracking of the coefficients or sets. It is known that list-based MT-SP-HSICA has a better coding memory requirement at low bit rates than the listless MT-SP-HSICA, but the demand for coding memory increases exponentially as bit rate.

The proposed compression algorithm has a fixed demand for memory (coding), which depends on the number of sub-bands present in one frequency frame. For the 'L' level of mathematical transform, the number of sub-bands is $(3L+1)$, and each coefficient has '8' bits. For each frequency frame, 18 bytes of extra coding memory is required for some other computations. Thus, the required coding memory for the 128 frequency frames is $'[8(3L+1) + 18] \times 128'$. Table 8 shows that the proposed HSICA has a minimal requirement of the coding memory of 18.25 KB. It outperforms the other compression algorithms but has little more than those of Bajpai et al. [69] Bajpai and Kidwai [70].

5.8. Coding Complexity

The coding complexity of any compression algorithm is measured by the time required to encode and decode to convert the transform coefficient to the bit stream and vice versa [90]. Table 9 (encoding time) and Table 10 (decoding time) show that decoding always takes less time than encoding. It has been clear that the coding complexity has been reduced significantly. The amount of time necessary to convert the transform HS image to the encoded embedded bit stream is the encoding time. At the same time, the decoding procedure takes to reconstruct the HS picture from the data received in the bit stream. From the decoding time and encoding time, it has been noted that listless MT-SP-HSICA has a low coding time requirement while list-based MT-SP-HSICA time requirement increases rapidly for the higher bit rates. Regarding coding complexity, the proposed algorithm outperforms the FrWF-based compression algorithm [70] due to the use of buffer memory, and for another list-based, MT-SP-HSICA performs better. Table 11 presents the comparative analysis of the listless compression algorithms for the different HS image sizes Figure 2. Figure 2 displays the original HS image and the reconstructed HS image after compression for the Uncalibrated Yellowstone Scene 00 at a CR of 16.

6. Conclusion

HS images have great potential in many fields and are a powerful, non-destructive assessment technique. However, a huge amount of HS image data generated by the HS image sensors is hard to process [95]. Hence, to make HS images

accessible to all, reducing HS image data is mandatory, and it should also work with low-resource HS image sensors. Many HSICAs were proposed in the past, but they are either complex in execution nature or have low coding efficiency. The present manuscript proposed a compression algorithm with low transform memory and computational complexity. It is due to the reduction in the multiple memory access, which makes the compression algorithm fast.

Acknowledgement

The authors thank Integral University for providing MCN “IU/R&D/2025-MCN0003634”.

Declarations

Author Contributions

Rajesh and Shrish Bajpai developed the algorithm, simulated the algorithms, and prepared the manuscript, while Naimur Rahman Kidwai edited the manuscript.
